1 Introduction

Since the industrial revolution, engines and machines have been the driving force for economical growth across industries such as automotive, airline, oil and gas, to name a few. However, machines are prone to failure and must be monitored and maintained regularly to avoid catastrophic failure leading to significant financial and human loss. To mitigate equipment and machine proclivity toward failure, a process called predictive maintenance has been developed within the industrial community. Predictive maintenance for machines and industrial equipments can be defined as a maintenance philosophy or more generally a framework with a set of methods used to predict and prevent machine failure in order to avoid unexpected downtime and reduce related human and financial cost. This maintenance philosophy, when correctly implemented, increases machine life time, and reduces maintenance cost [reference].

As a framework, predictive maintenance has 4 levels. In level 1, visual inspection of machines or equipments are performed in order to assess any damage. In addition, equipment must fail before they are replaced, which can incur a high production cost. In level 2 and 3, machine characteristics such as vibration, temperature, electrical current, voltage etc are monitored continually or periodically depending on their criticality. This is called condition monitoring. In condition monitoring, the goal is to detect any change in machine normal behaviour, in order to detect failure as early as possible and schedule maintenance accordingly. Maintenance actions are performed periodically regardless of machine health condition. In level 4, big data and machine learning are the main driving forces in detecting failure and planning maintenance. At this level, maintenance actions are not performed periodically but are planned according to machine health condition derived from the application of anomaly detection techniques. This reduces unnecessary maintenance actions and significantly cuts down maintenance cost as well as increasing machine life time.

According to PriceWaterhouseCoopers (PWC), one of the four largest auditing and consulting companies in the world, a survey from 280 companies in Belgium, Germany and the Netherlands, revealed that only 11% of companies have reached level 4 [4]. The application of level 4 requires collecting, saving and analysing large amounts of data, from which maintenance decisions can be made. Anomaly detection methods and more generally supervised and unsupervised learning methods are used in the analysis phase.

In supervised learning, based on available failure data from a defective machine, a learning algorithm is trained to recognise the failure pattern in the data. This is sometimes achieved by fitting the algorithm parameters to the data, which results in a model called a classifier or a regressor. A classifier is a model derived from a classification algorithm while a regressor is a model derived from a regression algorithm.

In machine learning, the failure data is called a labeled data because we can assign a categorical label such as fail or a numerical label such as 1 to specify the condition of the

machine through the data measuring its characteristics. In the absence of labeled data, unsupervised learning methods can be apply to detect pattern in the data without prior knowledge to classify data regions as anomalous or not. One such technique is clustering algorithm where the input data is separated into subregions.

The procedure of classifying a data region as anomalous or not is called anomaly detection. An anomaly is defined as a pattern in the data, that does not conform to expected normal behaviour [3]. A general anomaly detection strategy will first detect normal behaviour, secondly set a boundary around the normal behaviour and finally declare any data out of the boundary as anomaly.

Several factor make this general approach of anomaly detection challenging: The notion of anomaly is different for different application domain and not all application domain have enough labeled data to train a supervise learning algorithm [3]. An extensive survey from [3] revealed that the majority of research have been focussing on simple anomalies while most application domain are faced with complex anomalies. There are mainly three types of anomalies: Point anomalies which are simple anomalies, contextual and collective anomalies which are complex anomalies [3]. When one data point in a time series is anomalous with respect to the other data points, we have a point anomaly. In a contextual anomaly, a data instance is anomalous relative to a context. For example the vibration of a machine might be very high if the load increase suddenly, and decrease when the load goes back to normal. But if the vibration increases monotonously regardless of the load, then we have a contextual anomaly. If a collection of related data instance is anomalous with respect to the entire data set, it is termed a collective anomaly [3].

In rotating machines, more than 40 % of anomalies can be attributed to bearing defect [references].

Figure 1: Defect statistic, taken from [reference]

In this project we present a mixed methodology to detect and predict bearing defects. The methodology consists of using signal processing for feature generation and data labelling, and machine learning for defects classification and failure prediction. For a given input dataset, the dataset is decomposed into its subcomponents or basis components. The basis components also called features are then used as input of a supervised learning algorithm for defect classification and failure prediction.

The signal processing methods used are Fourier transform, wavelet transform and Hilbert Huang transform. We focus on ensemble learning and feed forward neural network for classification. Furthermore we show that the back-propagation process in the feed forward neural network can be modelled by an ordinary differential equation, whose solution represents the path of the hidden and output layer weights.

This thesis is structured into five parts organised as follows. In chapter one we give an overview of the signal processing methods. Chapter two outlines the machine learning methodology and shows that the back-propagation in the feedforward neural network can be modelled as a differential equation. We present a case study in chapter three and apply the methodology defined in chapter one and two. The thesis is concluded in chapter four where we ...

3.1 A general anomaly detection methodology

3.2 A novel anomaly detection strategy for predictive maintenance

4 Signal processing methods

4.1 Overview

In this section, we present three signal processing methods to generate new feature for anomaly detection. In the context of this work, a feature is a numerical sequence that represents the state of a system. For example, voltage and vibration measurement taken from a motor over time are time series that we call feature. These two features contain information about the state of the motor, the latter being the system in this case. By state we mean the current health of the motor. The health of the motor is represented by a health index which is a numerical value that quantifies the overall health of the motor.

Generating new feature from existing one, is a common procedure in machine learning. For example, by using Fourier transform, we can generate the frequency spectrum of a vibration time series. The frequency spectrum is the set of all frequency from each vibration component of the original vibration time series. If the motor is anomalous, the anomaly will generate an extra component in the vibration time signal, and the corresponding anomalous frequency will be visible in the frequency spectrum. Wavelet and Hilbert Huang transform can also be used to generate new feature for anomaly detection.

In the rest of this section we cover Fourier transform, wavelet transform and Hilbert Huang transform. For each transform, we establish the theoretical background followed by a direct application of the transform.

4.2 Fourier transform

4.2.1 Theory

The bulk of Fourier analysis is to decompose a time signal into its multiple frequency component. Let $X(t)$ be a time signal, that is a function that maps time to real numbers. Mathematical we can write

$$X(t) : [0, T] \rightarrow \mathbb{R} \quad (1)$$

4.2.2 Application

In this approach we use Fourier transform to detect defect frequency such outer race defect frequency and inner race defect frequency in the envelop spectrum. In this case the envelop

spectrum is the new feature generated from the original vibration data. The bearing type used are Rexnor ZA-2115. For this type of bearing, the constant defect frequency (cdf) for ball pass frequency outer race defect is 0.1182 and the constant defect frequency for ball pass frequency inner race defect is 0.1484 [reference]. According to Rexnord product engineering group [reference], to find the defect frequency in Hz we multiply the constant defect frequency (cdf) by the rotational speed of the bearing (here 2000 RPM), to find the defect frequency in Hz. Note that the defect frequency is computed from the geometry of the bearing, which means that for a specific bearing, this is a constant value.

Figure 2 shows the geometry of a bearing, from which bearing defect frequency can be computed. Figure 3 illustrates how Fourier transform can decompose vibration data into its frequency components. Each frequency component which are trigonometric functions are characterised by constant frequency and amplitude. In a defect bearing, the defect frequency will be coupled with a relatively high amplitude.

Figure 2: Geometry of a bearing

Figure 3: Illustration of using Fourier transform to decompose a time signal to its frequency components

Next, we compute the envelop spectrum for each vibration signal by using the FFT method (Fast Fourier Transform). The envelop spectrum is used to detect early sign of failure. Recall that a vibration signal can be decomposed into its sub components, where each sub component is characterised by its frequency and its amplitude. Early sign of failure can be seen in the high frequency low amplitude sub component. As the failure becomes more pronounced, it becomes visible in the low frequency high amplitude sub component. Figure 4 shows the raw vibration signal, the corresponding envelop spectrum and the ball pass frequency outer race defect.

Figure 4: Vibration time signal

By computing the envelop spectrum for each time signal and extracting the amplitude of a defect frequency we can visualise the severity of a defect. Figure 5 and ?? show the amplitude of outer race defect and inner race defect for four bearings and three bearings respectively. In Figure 5 we can observe that bearing number one is affected severely by ball pass frequency outer race defect. Figure 6 shows that bearing number three has ball pass frequency inner race defect.

Figure 5: Ball pass frequency outer race detection

Figure 6: Ball pass frequency inner race detection

4.3 Wavelet transform

4.3.1 Theory

4.3.2 Application

In the wavelet transform we generate two extra features from the vibration time signal, namely the discrete detailed coefficient cD and the approximate coefficient cA . The detail coefficient cD represents the high frequency component of the vibration time signal and the approximate coefficient cA represents the low frequency component. For the mother wavelet we use Daubechies 20 or $db20$ shown in Figure 7

Figure 7: The scaling function φ (left) and the wavelet function Ψ (right)

Once we have the two extra features, we compute the dissimilarity between a reference sample and subsequent samples for each feature. This process generates a set of points (x, y) that represent the health index of each sample. From Figure 8 and 9, we can observe that bearing number four and bearing number three suffer from ball pass frequency outer race and ball pass frequency inner race defect respectively. We can also observe that a bearing can go through three main stages:

1. A healthy stage characterised by a low health index
2. A warning stage characterised by an increasing health index
3. An alarm stage characterised by a high health index

Figure 8: Ball past frequency outer race defect detection from wavelet transform

Figure 9: Ball past frequency outer race defect detection from wavelet transform

In the alarm stage, as the degradation becomes more severe, the distance between the points increases.

4.4 Hilbert Huang transform

4.4.1 Theory

The Hilbert-Huang transform is a data decomposition methods that consists of decomposing data in an adaptive fashion. Adaptivity means that rather than imposing an a priori basis such as trigonometric functions, a posteriori basis functions are derived from the data itself [1]. In doing so, the method deals better with nonlinearity and non stationarity which are inherently present in real world data.

This method gives an alternative approach of time-frequency-energy paradigm by using Hilbert spectral analysis and the so call empirical mode decomposition (EMD) to express the nonlinearity and the non stationary in data with instantaneous frequency and instantaneous amplitude [1].

The empirical mode decomposition (EMD) originated from the quest of functions that can be expressed by a time-frequency-amplitude expression, such that the frequency is physically meaningful. Consider a time series $x(t)$. Its Hilbert transform $H(t)$ is given by

$$H(t) = \frac{1}{\pi} P \int_{-\infty}^{\infty} \frac{x(\tau)}{t - \tau} d\tau, \quad (2)$$

where P is the Cauchy principal value. The corresponding time-frequency-amplitude function of $x(t)$ is the analytical function

$$z(t) = x(t) + iy(t) = a(t)e^{i\theta(t)}, \quad (3)$$

where the instantaneous amplitude $a(t)$ and phase $\theta(t)$ can be computed by

$$a(t) = \sqrt{x(t)^2 + y(t)^2} \quad (4)$$

$$\theta(t) = \tan^{-1} \left(\frac{y(t)}{x(t)} \right). \quad (5)$$

Furthermore, the instantaneous frequency $w(t)$ can be derived from the phase $\theta(t)$ as

$$w(t) = \frac{d\theta}{dt}. \quad (6)$$

By setting

$$f(t) = \frac{y(t)}{x(t)},$$

the expression of the instantaneous amplitude $w(t)$ in (6) can be expanded as

$$w(t) = \frac{f'(t)}{1 + f(t)^2} = \frac{y'(t)x(t) - y(t)x'(t)}{x(t)(x(t) + y(t)^2)}. \quad (7)$$

The instantaneous frequency $w(t)$ using the Hilbert transform is not always physically meaning. For example for an arbitrarily function, the instantaneous physical frequency values should be positive. However this is not always the case.

For example if

$$f(x) = \cos(ct) + d \quad (8)$$

where c and d are constants, the instantaneous frequency is given by

$$w(t) = \frac{-c \sin(ct)}{1 + (\cos(ct) + d)^2} \quad (9)$$

Figure 10: function f and its corresponding frequency

From Figure 10, we see that the instantaneous frequency takes negative values, which is not physically meaning full.

To circumvent this, the Hilbert-Huang transform offers a methodology to obtain from an arbitrarily function or time series $x(t)$ a set of finite subcomponents whose instantaneous frequency are physically meaningful. This methodology let to the empirical mode decomposition.

The necessary condition for obtaining a physical frequency is that $x(t)$ satisfies the approximate local envelope symmetry condition [2].

This condition is expressed in the empirical mode decomposition (EMD) such that an arbitrarily time series $x(t)$ can be decomposed by a sifting process into intrinsic mode function c_i

$$x(t) = \sum_{i=1}^n c_i + r_n \quad (10)$$

where the c_i satisfies the approximate local envelope symmetry condition

$$SD_k = \frac{\sum_{t=0}^T}{\sum_{t=0}^T} < \epsilon \quad (11)$$

where ϵ is a small predefined real number.

4.4.2 Application for bearings fault detection

we consider a vibration signal with sample frequency of 20000Hz rotating speed of 2000 RPM

Figure 11: Vibration signal of 1 second snapshot

After applying the empirical mode decomposition on the vibration data from figure 11 we get sixteen intrinsic mode functions

Figure 12: 1th and 2nd intrinsic mode function (imf)

Figure 13: 3rd and 4th intrinsic mode function (imf)

Figure 14: 5th and 6th intrinsic mode function (imf)
